Summary

Aims: The present study aimed to analyze the acute glucose responses in the first and last sessions of four mesocycles along an aquatic aerobic training periodization.

Methods: Fourteen patients (6 men and 8 women; 54.3 ± 9.0 years; body mass index of 34.5 ± 3.9 kg/m²) with type 2 diabetes underwent a 12-week training program involving deep-water running. This exercise training was performed by an interval training method, with a frequency of 3 times a week, session duration of 35 minutes and intensity progressing from 85 to 90% to 95 to 100% of the anaerobic threshold heart rate (ATHR) along the periodization. Capillary glucose was assessed before and immediately after the first and last session of each mesocycle. A generalized estimated equation (time x session x mesocycle) was used to assess reductions in glucose levels in different sessions (first and last) along four mesocycles (α = 0.05).

Results: All sessions resulted in a reduction in glucose levels (time effect: p < 0.001), without differences between the first and last session of each mesocycle (session effect: p = 0.738). With regard to the mesocycles (mesocycle effect: p = 0.003), significant differences were found between mesocycles 2 and 3. In time*mesocycle interaction (p = 0.002), in most comparisons, post-session values were lowest that pre-session values, independently of mesocycle, except for the post-session value of mesocycle 3, which was similar to the pre-values of mesocycles 2 and 4.

Conclusion: Aerobic training in deep water with crescent linear periodization over 12 weeks is able to reduce glucose levels in patients with type 2 diabetes.

Key words: Aquatic environment. Exercise. Diabetes mellitus. Glycemia.

Respuestas de la glucemia aguda a lo largo del entrenamiento aeróbico en aguas profundas en pacientes con diabetes tipo 2

Resumen

Objetivo: Analizar las respuestas de glucemia aguda en las primeras y últimas sesiones de cuatro mesociclos a lo largo de una periodización de entrenamiento aeróbico acuático.

Métodos: Catorce pacientes (6 hombres y 8 mujeres; 54.3±9.0 años; índice de masa corporal de 34.5±3.9 kg/m²) con diabetes tipo 2 fueron sometidos a un programa de entrenamiento de 12 semanas de carrera en aguas profundas. Se realizó un entrenamiento aeróbico de intervalos, realizado 3 veces por semana, con sesiones de 35 minutos y la intensidad progresando a lo largo de la periodización desde 85% - 90% a 95% - 100% de la frecuencia cardíaca de umbral anaeróbico (FCUA). La glucosa capilar fue evaluada antes e inmediatamente después de la primera y la última sesión de cada mesociclo. Se utilizó una ecuación generalizada estimada (tiempo x sesión x mesociclo) para evaluar las reducciones en los niveles de glucosa en las diferentes sesiones (primera y última) a lo largo de cuatro mesociclos (α = 0.05).

Resultados: todas las sesiones resultaron en una reducción en los niveles de glucosa (efecto tiempo: p<0,001), sin diferencias entre la primera y la última sesión de cada mesociclo (efecto de sesión: p = 0,738). Con respecto a los mesociclos (efecto mesociclo: p=0.003) se encontraron diferencias significativas entre los mesociclos 2 y 3. En la interacción tiempo*mesociclo (p=0,002), en la mayoría de las comparaciones, los valores post-sesión fueron menores de los valores pre-sesión, independientemente de mesociclo, excepto para el valor después de la sesión del mesociclo 3, que fue similar a los valores antes de la sesión de los mesociclos 2 y 4.

Conclusión: Doce semanas de entrenamiento aeróbico en aguas profundas con la periodización lineal y creciente es capaz de reducir los niveles de glucosa en pacientes con diabetes tipo 2.
Introduction

Type 2 diabetes mellitus (T2DM) is a worldwide public health problem predominantly resulting from obesity and a sedentary lifestyle. Interventions ensuring lifestyle changes have been effective both in the prevention and control of the disease, with exercise being one of the most effective nonpharmacological treatments for T2DM\(^1,2\); through its beneficial effects on outcomes such as blood pressure, lipid profile and glucose levels\(^3\).

According to the American Diabetes Association (ADA), patients with T2DM should do 150 minutes or more of aerobic exercise at moderate intensity per week, and when without complications must combine this with two or three sessions per week of resistance training\(^4\). These guidelines demonstrate how important aerobic training is to this population, and it is generally recommended to all patients. However, despite a lot of evidence indicating the beneficial chronic effects, especially in glucose control in this population\(^5,6\), less is known about the acute glycemic effects of aerobic training during progressive training. Studies investigating this issue focused predominantly on the comparison between the effects of different exercise sessions in a specific training status\(^7,8\). To the best of the authors’ knowledge, no study has investigated these effects at different times during a periodization, in which the intensity and/or duration increases along the training while the patients improve their physical fitness and metabolic status.

With regard to the periodization of aerobic training, it is worth noting that patients with a type 2 diabetes clinical profile, usually obese or overweight, can complicate increases in exercise dosage, especially in intensity, because in greater intensity for glucose control, such as those near of anaerobic threshold\(^9\), patients are more susceptible to lower limb injury. An alternative to the necessary training progression is the training conducted in water, such as water aerobics, because the buoyancy provides attenuated impact forces, especially for the lower limbs\(^10\). Moreover, deep-water running is another interesting modality for the progression of exercise training because the practitioners perform aerobic exercise at high loads with reduced risk of injury, since a float vest is used to keep the body in an upright position, preventing contact between the feet and the bottom of the pool\(^11\).

Because of its characteristics, deep-water running is favorable to progress in training without increasing the impact on joints, thereby enabling patients to exercise at high intensity or for long duration, optimizing glucose control. In addition, this modality has demonstrated a similar increase in strength to combined training in water\(^12\) and has glycemic metabolism benefits in glucose-intolerant women\(^13\). The fact that this modality allows progression in training intensity, including for patients with difficulties in supporting their own body mass\(^14\), indicates the need for knowledge about the acute glycemic effect in different stages of a linearly increasing periodization, because although it seems a great alternative, literature about “exercise and type 2 diabetes” is scarce on studies in water. Thus, the present study aimed to analyze acute glycemic responses in the first and last sessions in four mesocycles of a deep-water running program. Our hypothesis is that in mesocycles of three weeks, the acute glycemic effect not is attenuated, being similar in the first and last session of each mesocycle.

Materials and methods

Subjects

The sample consisted of 14 patients with T2DM (6 men and 8 women) who had not undertaken any physical exercise in the previous three months and were receiving their usual medical treatment. Patients with the following conditions were excluded from the sample: uncontrolled hypertension, autonomic neuropathy, severe peripheral neuropathy, proliferative diabetic retinopathy, severe nonproliferative diabetic retinopathy, decompensated heart failure, limb amputations, chronic renal failure (MDRD-GFR < 30 ml/min)\(^15\) or any muscle or joint impairments that prevented individuals from engaging in physical exercise. The presence of these conditions was confirmed by medical history as well as clinical and laboratory examinations. All patients had undergone effort electrocardiograms in the six months preceding the study.

Research design

Patients were identified from the records of the Endocrine Division of a tertiary hospital and were also recruited through advertisements in local newspapers between June and July 2012. All participants were fully informed of the procedures involved in the study, and provided written consent prior to participation. The study was approved by the Research Ethics Committees of the Universidade Federal do Rio Grande do Sul (protocol number 108.997) and of the Hospital de Clínicas de Porto Alegre (protocol number 54475). The research design, with intervention and evaluations performed are illustrated in the Figure 1.

Anthropometric measurements

Prior to the intervention, patients underwent anthropometric measurements. Body mass and height were assessed using a digital scale and a stadiometer (FILIZOLA; Sao Paulo, Brazil). These values were used to calculate patient body mass index (BMI) using the following formula: mass (kg)/height² (m). Waist circumference was measured at the midpoint between the iliac crest and the last rib. Additionally, skinfolds were measured at the following eight sites: tricipital, subscapular, suprailiac, abdominal, chest, midaxillary, thigh and leg. The equations proposed by Petroski\(^16\) were used to estimate the body density of men and women, while body fat percentages were estimated using the Siri formula\(^17\).

Blood analysis

Blood samples (4ml) were obtained from an antecubital vein after fasting for 12 to 14 h. The samples were collected in tubes with EDTA and kept frozen at -80 °C as total blood (without centrifugation). After blood data collection, the levels of HbA1c were determined through high-performance liquid chromatography (HPLC) to characterize the glycemic control of the patients.

Capillary glycemia

Capillary glycemia was assessed before and immediately after the first and last sessions of each training mesocycle using a clinical

Glucometer (Accu-Check Performa, Roche, São Paulo, Brazil), which assesses glycemic levels in approximately 5 seconds, and a lancet device (Accu-ChekMulticlix, Sao Paulo, Brazil).

Intervention

Patients underwent 12-week training program involving deep-water running with a life vest. The interval-training program consisted of four mesocycles of three weeks each. Training was conducted three times per week (Monday, Wednesday and Friday), and each 45-minute session was divided into a warm-up period (5 min), followed by the main training program (35 min) and a cool-down section (5 min). The intensity of the physical exercise prescribed was adjusted according to each subject’s heart rate deflection point (HRDP), which was determined by a progressive maximal test conducted in the water environment. This method was chosen due to its ease of application and association with the second ventilatory threshold, a precise indicator of the relative stress caused by exercise. Participants were asked to wear HR monitors (RSX 300, Polar) during the exercise sessions to control training intensity. Each individual was asked to read and report their heart rates to one of the three instructors who supervised the exercise sessions. Each instructor then used a table containing subjects’ training heart rate ranges to provide feedback on the recommended exercise intensity for each patient. The 12-week training program prescribed to each participant is described in Table 1.

Statistical analysis

Descriptive data of the subject characteristics are presented as mean and standard deviation for continuous variables and as n for categorical variables. Glycemic levels are presented as mean and standard error. A generalized estimation equation (GEE) was used to assess alterations in glucose levels (pre versus post) in different sessions (first and last) in each mesocycle of training, taking into consideration the three factors involved in the analysis (time, session and mesocycle). Given that exogenous insulin use could potentiate an exercise glucose-lowering effect, we performed the analyses for all patients, and excluding those patients using insulin. Multiple comparisons were performed with Bonferroni correction. The level of significance was set at $\alpha = 0.05$. All analyses were performed using the Statistical Package for the Social Sciences (SPSS) software, version 19.0.

Figure 1. Study design (evaluations and intervention).
Results

Sample data regarding disease duration, age, anthropometric measurements and medication use are shown in Table 2.

Table 2. Subject characteristics.

| Age (years)  | 54.3 ± 2.4 |
| Duration of DM2 (years) | 5.4 ± 1.0 |
| HbA1c (%) | 7.9 ± 0.7 |
| Body mass (kg) | 93.1 ± 3.6 |
| Body mass index (kg.m⁻²) | 34.5 ± 1.0 |
| Waist circumference (cm) | 111.7 ± 2.9 |
| WHR | 0.68 ± 0.02 |
| Fat mass (%) | 37.5 ± 1.1 |
| Sex (male/female) | 6/8 |
| Medical treatment | |
| Metformin (n) | 12 |
| Sulphonylurea (n) | 6 |
| DPP-4-inhibitors (n) | 1 |
| Pioglitazone (n) | 1 |
| Diuretics (n) | 4 |
| Beta blockers (n) | 4 |
| ARAs II (n) | 4 |
| Acetyl-acetylsalicylic (n) | 5 |
| Statins (n) | 7 |
| Insulin (n) | 3 |

DPP-4: dipeptidyl peptidase-4; ARAs: Angiotensin receptors antagonists; WHR: waist/height ratio; Values of age, duration of DM2 and anthropometric measures are expressed as the mean ± SE; Values of sex and medication are expressed by n.

All training sessions determined a reduction in glucose levels (time effect: p < 0.001). In all mesocycles, the first session values did not differ from the values found in the last session (session 1 = session 9, session 10 = session 18, session 19 = session 27, session 28 = session 36; session effect: p = 0.738). Between the mesocycles (mesocycle effect: p = 0.003), significant differences were found only between the pre-session values of mesocycles 2 and 3 (Table 3). In time*mesocycle interaction (p = 0.002), significant differences were found between pre-session and post-session values in most comparisons, except for the post-session value of mesocycle 3, which was similar to the pre-values of mesocycles 2 and 4.

Given that exogenous insulin use could potentiate an exercise glucose-lowering effect, we performed an analysis excluding those patients using insulin. The results, however, were very similar: Exercise sessions determined reductions in glucose levels (time effect: p < 0.001), without differences between the first and last session of each mesocycle (session effect: p = 0.889). Between the mesocycles (mesocycle effect: p = 0.018), significant differences were found only between the pre-session values of mesocycles 2 and 3 (Table 4). In time*mesocycle interaction (p = 0.012), significant differences were found between pre-session and post-session values in most comparisons, except for the post-session value of mesocycle 1, which was similar to the pre-value of mesocycle 2.

No hypoglycemic episodes or other adverse effects were reported over the course of the study.

Discussion

This study showed that acute exercise sessions performed in an aquatic environment are effective in reducing glycemia. The mesocycle composition of three weeks was enough to maintain the glucose mag-
Acute glycemic outcomes along the aerobic training in deep water in patients with type 2 diabetes

Magnitude reduction during the mesocycles, without deteriorating effects as the patients adapted to the session model. The increasing intensity between the four different mesocycles was able to continue to impact glucose levels beneficially during the 12 weeks, underlining the similarity of post-exercise values in the third mesocycle to pre-exercise values in the fourth mesocycle, indicating a possible training adaptation.

Glucose reduction after training sessions has been the target of many investigations. However, the aim of these studies is usually to compare the acute glycemic effects of different modalities. In this context, aerobic training has shown a greater glucose reduction than resistance training and a similar glucose reduction to combined training with a similar duration (40 min). Bachi et al. reported an area under the curve of glucose during 60 min of aerobic exercise lower than that observed during 60 min with no exercise. Figueira et al. found a glucose reduction of approximately 16% after sessions in both aerobic and combined training, a reduction that was sustained for only three hours after the end of the sessions. However, these investigations are restricted to land, which creates difficulties in performing exercise for some patients, because the disease is usually associated with obesity, sarcopenia, muscle weakness and chronic complications characteristic of the disease, such as peripheral neuropathy which end up limiting this population’s adherence to exercise programs. These patients’ clinical profile emphasizes the importance of our findings, because we found an expressive glucose reduction (average of the eight deltas in capillary glucose has not been sufficiently studied in patients with type 2 diabetes, but with a similar magnitude of glycemic reduction. While Terada et al. adopted a progression focused on the duration of the training sessions, the present study adopted a progression based especially on intensity. Both strategies of periodization seem appropriate, and can be used as needed. The different progressions can be adapted to the profile of patients: While subjects with limitations for training at high intensity (i.e. land-based exercise, leading to higher joint impact) can progress in training duration, subjects with little available time for training may fix the duration of sessions and increase the intensity.

In conclusion, deep-water aerobic training with an increasing linear periodization, especially progressive in intensity every three weeks, is...
able to reduce glucose levels in patients with type 2 diabetes over 12 weeks – important information for structuring training aimed at controlling the glucose levels in this population. These findings suggest the need for further studies investigating glycemic behavior at the beginning and end of training cycles with different durations (>3 weeks), aimed at widening knowledge of the influence of different training adaptations on the effects of acute exercise on blood glucose levels.
